Abstract

Liver abscess is defined as a pus heap in a newly formed cavity at the expense of surrounding liver tissue which gets destroyed or repressed. It is a rare and serious infection. The aim of our survey is to report the clinical characteristics as well as biological, imagery and therapeutic ones of liver abscesses in diabetic patients. It is a descriptive and analytical survey including all diabetic patients followed in the Endocrinology and Diabetology Department of Ibn Rochd University Hospital of Casablanca with liver abscess from March 2013 till March 2016. The studied variables concern mainly age, gender, diabetes type, glycated hemoglobin (HbA1c), clinical signs, isolated germ and treatment.

During the studied period, 11 patients were followed for liver abscesses. They were two women and nine men. Mean age was 49 ± 11 years. They were all in poor glycemic control and admitted in ketosis with fever. Clinical exam did not lead to any infections focus. The assessment indicated leukocytosis with neutrophil predominance and an increase in C-reactive protein. Due to the persistence of general condition alteration of the patients, an abdominal ultrasound was performed in all patients and revealed hypoechochogenous images in relation with liver abscesses confirmed by abdominal tomodensitometry.

The bacteriological/parasitological exam detected *Klebsiella pneumoniae* in five cases, *Escherichia coli* in two cases, *Entamoeba histolytica* in two cases and was sterile in two cases. The patients underwent intensified insulin therapy, empiric intravenous antibiotic therapy and were then adapted according to the results of antibiogram. Five patients underwent surgical drainage and two patients ultrasound guided drainage. Evolution was favorable in all patients. Liver abscesses in diabetic patients are pauci-symptomatic. It should be then considered in case of unfavorable evolution of acute decompensation despite a well conducted therapy when patients have a chronic poor glycemic control.

Keywords: Diabetes-liver abscess-poor; Glycemic control-infection; Pauci-symptomatic

Introduction

Liver abscess is defined as a pus heap in a newly formed cavity at the expense of surrounding liver tissue which gets destroyed or repressed [1]. Bacterial liver abscesses prevalence varies from 0.29 to 1.47% in autopsies series and from 0.008 to 0.16% in hospitalized patients [2]. In certain cases liver amoebic abscesses can complicate intestinal amoeba in 3 to 9% of cases [3]. Diabetic patients seem to be the most favorable to liver abscesses with 3.5 fold relative risk [1]. Clinical manifestation is pauci-symptomatic and no specific. Germs can be bacterial, parasitic or fungal. It is a rare and serious infection. Treatment is based on empiric antibiotic therapy adapted to antibiogram and draining according to cases.

The aim of our survey is to report the clinical, biological and imagery characteristics of liver abscesses in diabetic patients.

Patients and Methods

It is a descriptive and analytical survey including all diabetic patients followed in the Endocrinology and Diabetology Department of Ibn Rochd University Hospital of Casablanca with liver abscess from March 2013 untill March 2016. Liver abscess diagnosis was maintained in case of an evoking hypoechochogenous mass at the hepatic ultrasound. The studied variables concern mainly age, gender, type of diabetes, glycated hemoglobin (well glycemic control: HbA1c <7%, poor glycemic control: HbA1c >7 %), clinical signs, isolated germ, treatment and evolution were excluded any patient who refuses to provide the information.
**Results**

**Epidemiological features**

In all, 1702 patients were hospitalized for diabetes which followed for liver abscesses. Prevalence was 0.6%. They were two women and nine men. Mean age was 49 ± 11 years with a mean history of 4.6 ± 3.6 years. Nine patients had type 2 diabetes and two patients had type 1 diabetes. They were all in poor glycemic control with mean glycated haemoglobin of 10.6 ± 1.4%. The (Table 1) illustrates the patients features.

**Clinical features**

Patients were all admitted in ketosis with fever, general condition alteration and no abdomen pain. Clinical exam did not lead to any infection focus except in two patients who showed diffuse abdominal sensitivity at examination.

**Biological characteristics and imagery**

Initial assessment indicated leukocytosis with neutrophil predominance and a mean rate of 24200 elements/mm³, an increase in C-reactive protein (CRP) of 188 mg/l. Liver transaminases were raised in three patients less than two folds the upper normal limit. Blood culture was negative in 8 cases and positive in three patients (K. pneumoniae: 2 cases, E. coli: 1 case).

Due to the persistence of general condition alteration, an abdominal ultrasound was performed and revealed hypoechochogenous images in relation with liver abscesses confirmed by abdominal tomodensitometry. The liver abscess was unifocal in six cases (Figure 1) and multifocal in five patients (Figure 2). Average size of the abscesses was 7.9 ± 3.6 cm. We noticed existence of gallstones in two cases. Furthermore prostatic abscess and right renal abscess were also identified in one patient.

Bacteriological/parasitological exam of the pus detected K. pneumoniae in five cases, E. coli in two cases, E. hystolytica in one case. Retroviral infection (HIV) serology, hepatitis (A, B and C), hydatic and amoebic serology ones were negative in ten cases and positive (amoebic serology) in one patient.

**Treatment**

Patients underwent intensified insulin therapy, empiric intravenous antibiotic therapy based on ceftriaxone, gentamycin and metronidazole, then adapted according to the results of antibiogram. Treatment duration was maintained during 4 to 6 weeks by intravenous way. Five patients underwent surgical drainage and two patients ultrasound guided drainage.

**Evolution**

It was favorable in all patients and an average length of hospital stay was forty five days.

Discussion

Patients mean age in our study was 49 ± 11 years. This result is close to the affirmation of Chagneau-Derrode Cet al. [4] who said that the peak incidence of bacterial liver abscess was between 60 and 70 years. Likewise we noted the male predominance which was found by Lin et al. [5] and Wang et al. [6].

Those found that gallstones, intra-abdominal infections, digestive surgery and pathologies leading to the immunosuppression including diabetes can lead to pyogenic liver abscesses [7,8]. In our series, diabetes and two cases of gallstones were found. It was described that leukocyte adherence, chemotaxis, phagocytosis and antioxidant systems involved in bactericidal activity may be impaired in diabetic patients [5].

It appears that our patients’ clinical features were insidious and no specific and only imagery (ultrasound and tomodensitometry) led to diagnosis. Thus we need to realize the importance of an abdominal ultrasound in every febrile diabetic patient with no evident clinical focus.

Bacteriologically, in more than 2/3 of the cases, the germ was identified in the liver abscess via pus exam or hemoculture [9]. E. coli was the main germ identified in the liver abscesses till 1980 when several studies started to report K. pneumoniae predominance (50 to 80%) in several countries. It is also what has been reported in several Asian studies mainly in Taiwan and Korea [5,6]. In our series, we also noticed the predominance of K. pneumoniae (five cases) followed by E. coli (two cases) and E. hystolytica (two cases). Diabetes is known as the main risk factor of liver abscesses with K. pneumoniae [6,10]. Thus, 25% of the patients with liver abscesses with K. pneumoniae were diagnosed for the first time for diabetes according to Yi-Tzung Lin et al. [5]. The serotype was not sought in our patients but in literature, there are K1 and K2 serotypes which are predominant.

Patients with poor glycemic control are more exposed to have complications such as liver veins thrombophlebitis, gangrene and spreading to other organs especially eyes, brain, urinary tract and lungs when causative agent is K. pneumoniae [5,11]. One of our patients showed a prostatic abscess combined to a right renal abscess that might be metastases from liver abscess with K. pneumoniae.

Therapeutically, concerning the draining of the liver abscess, there are no consensus recommendations. However, we know that antibiotic therapy alone is effective when the size of the abscess is lower than 3-5 cm. In an investigation involving 107 patients with liver abscess, Hope et al. [12] described a 100% success ratio when antibiotic therapy alone was carried out to treat unilocular liver abscess of less than 3 cm. The same was for 465 abscesses of which 176 liver abscesses in a study by Bamberger [13], therapeutic success rate was more than 80% by using antibiotic therapy alone when liver abscesses size is lower than 5 cm. According to the size of the abscesses, five patients underwent laparotomy drainage and two patients had ultrasound guided drainage.

In general, the empirical antibiotic therapy takes into considerations agents that are potentially responsible like aerobic gram-negative bacteria and streptococcus. Combination of amoxicillin with clavulanic acid or third generation cephalosporine or piperacillin or tazobactam with aminoside (gentamycin) are thus used empirically; metronidazole can be associated if the selected antibiotic is not active on the anaerobics or in case of doubt with amoebic abscess. The length of the antibiotic therapy generally varies from 3 weeks to 6 weeks [7,12,13]. In case of confirmed amoebic abscess, metronidazole is the favorite therapy. It is 1.5 to 2 g/day orally or intravenously for 10 days. Tinidazole or ornidazole in 1.5g/day for 5 days can be an alternative. The therapy is completed by a cure of contact amoebicid: tiliquinol, tilbroquinol (four tablets/day for 10 days) [14].

The long-term hospitalisation in our series could be explained by the poor glycemic control noted in all patients. So in diabetic patients with sepsis, Gornik et al. [15] demonstrated that HbA1c is an independent prognostic factor for hospital mortality and length of stay. Hyperglycaemia influences via advanced glycation end products (AGE) numerous physiological processes important in systemic inflammatory response and sepsis. AGE receptors have also been shown to negatively influence outcome of sepsis in animal model [16].

Mortality is high in diabetic patients and varies from 1% to 31% for pyogenic abscesses [17-20]. It is half reduced for the amoebic abscesses [2].

Conclusion

Liver abscesses in diabetic patients are pauci-symptomatic. Contrast between clinical and imagery is noticeable. It should be then considered in case of unfavorable evolution of acute decompensation despite a well conducted therapy when patient had a chronic poor glycemic control. Treatment goes through empirical antibiotic therapy adapted to antibiogram and draining according to abscesses sizes.
